FLOWCHART AND PSEUDOCODE

FLOWCHART AND PSEUDOCODE

- We will only go through some basic example: Calculate the Interest of a Bank Deposit

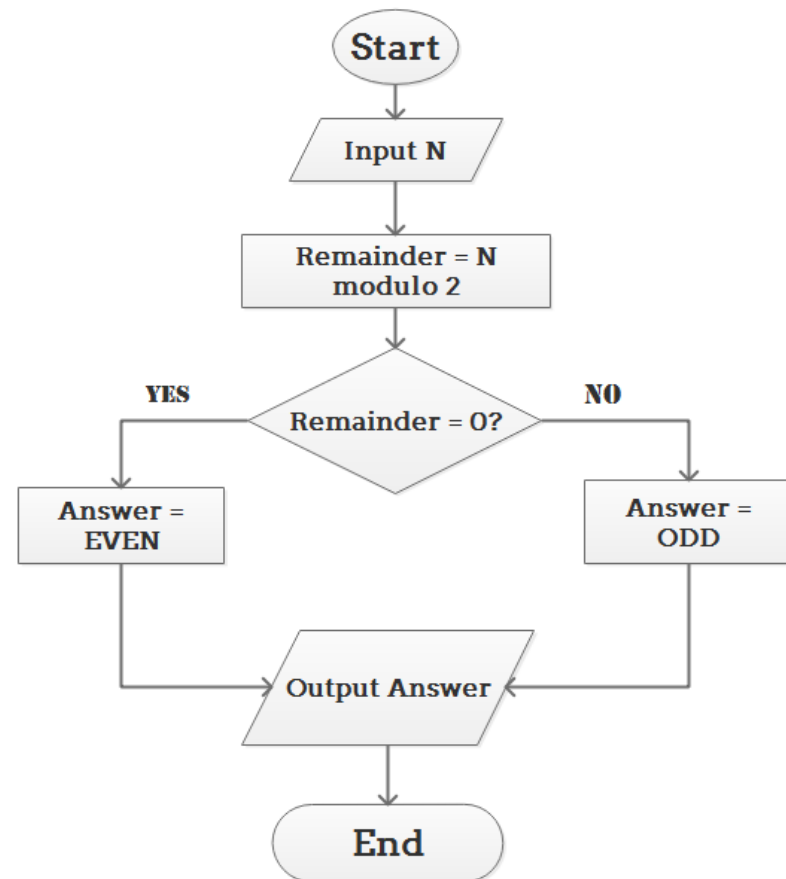

Step 1: Read amount,
Step 2: Read years,
Step 3: Read rate,
Step 4: Calculate the interest with formula
"Interest=Amount*Years*Rate/100
Step 5: Print interest,

FLOWCHART AND PSEUDOCODE

- Determine and Output Whether Number N is Even or Odd

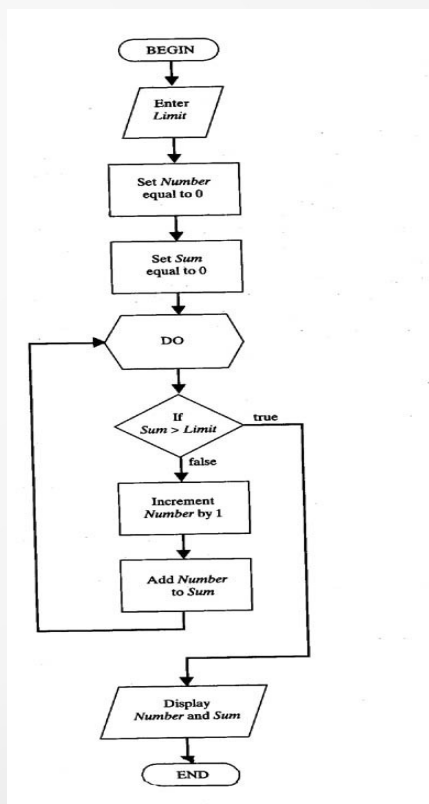

Step 1: Read number N,
Step 2: Set remainder as N modulo 2,
Step 3: If remainder is equal to 0 then number N is even, else number N is odd,
Step 4: Print output.

FLOWCHART AND PSEUDOCODE

- For a given value, *Limit*, what is the smallest positive integer **Number** for which the sum $\text{Sum} = 1 + 2 + \dots + \text{Number}$ is greater than *Limit*. What is the value for this **Sum**?

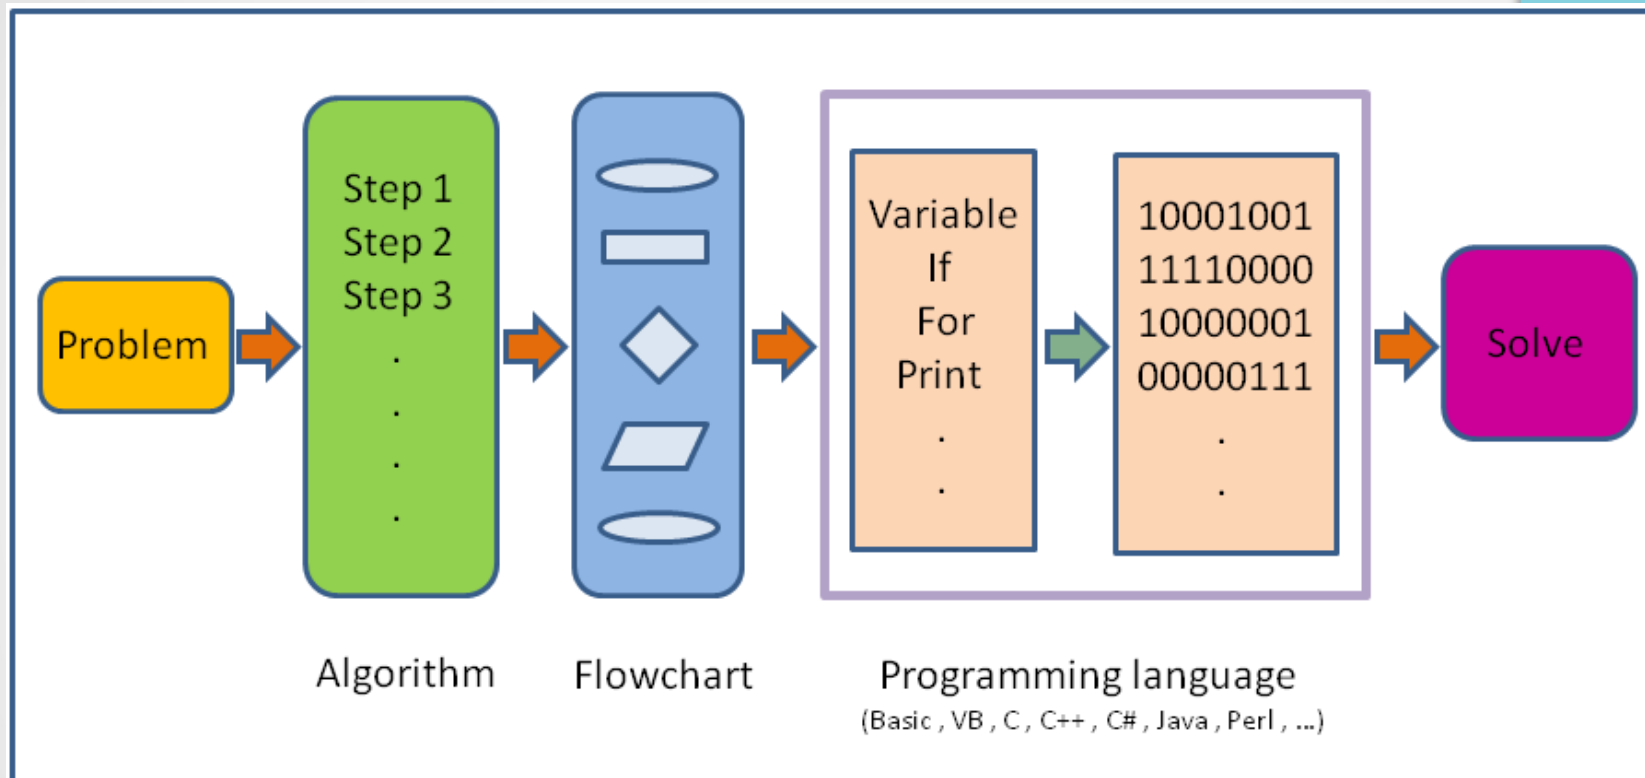

- Enter *Limit*
- Set *Number* = 0.
- Set *Sum* = 0.
- Repeat the following:
 - If $\text{Sum} > \text{Limit}$, terminate the repetition, otherwise.
 - Increment *Number* by one.
 - Add *Number* to *Sum* and set equal to *Sum*.
- Print *Number* and *Sum*.

CONTROL STRUCTURES

CONTROL STRUCTURES

There are three fundamental structures that are used for the algorithmic resolution of problems: **selection, iterations and sequence** (sequence of instructions) (the GOTO present in machine languages since the 70s has been progressively discouraged / eliminated)

Examples: <https://bitbucket.org/lstorchi/teaching>
<https://github.com/lstorchi/teaching>

SEQUENCES

Sequences

- **Sequence control structure** refers to the line-by-line execution by which statements are executed sequentially, in the same order in which they appear in the program. They might, for example, carry out a series of read or write operations, arithmetic operations, or assignments to variables.

Step 1: Read amount,

Step 2: Read years,

Step 3: Read rate,

Step 4: Calculate the interest with formula

$\text{Interest} = \text{Amount} * \text{Years} * \text{Rate} / 100$

Step 5: Print interest,

SELECTION

Selections

- The general structure of a selection instruction is as follows:

```
if (condition 1)  
    statements 1  
else if (condition 2)  
    statements 2  
...  
else  
    statements N  
endif
```

There can be so many else if

They do not necessarily have to show all three elements, if, else if and else, I can also have just a single if

Selections

- **Nesting**, I can nest the selection instructions of course:

if (condition 1)

statement 1

if (condition 2)

statements 2

end if

else

statements 3

end if

Operators

- In all programming languages, I can use relationship operators to compare numbers and variables, for example:

Description	Java, C, C++	Fortran
Greater than	>	.GT.
Greater than or equal	>=	.GE.
Less than	<	.LT.
Less than or equal	<=	.LE.
Equal	==	.EQ.
Not Equal	!=	.NE.

```
Int a;  
  
a = 4 // operatori di assegnazione  
  
If (a == 5)  
{  
    cout << "Hello" << std::endl;  
}  
else if (a > 5)  
{  
    cout << a << " > 5 " << std::endl;  
}
```

Logical Operators

- I take for granted the logical operators AND, OR and NOT

Logical Operators		
Operator	Description	Example
&&	AND	x=6 y=3 x<10 && y>1 Return True
 	OR	x=6 y=3 x==5 y==5 Return False
!	NOT	x=6 y=3 !(x==y) Return True

Examples the following expression

$5 < a < 7$

In programming languages it is broken into two elementary expressions linked by the operator AND:

$(a > 5) \text{ AND } (a < 7)$

Bitwise operations

- Do not confuse the previous with the bitwise operations
- These are the operations that are used to manipulate bitwise data, not to be confused with quanto seen in the previous slide
 - & (AND)
 - | (OR)
 - ^ (XOR I.e. 1 XOR 1 is zero)
 - ~ (ones' complement i.e. 0 to 1 and 1 to 0)
 - >> (right shift 11100101 >> 1 is 01110010)
 - << (left shift)

Bitwise operations

- A simple test just to clarify

```
└─ $ python3
Python 3.6.9 (default, A
[GCC 8.4.0] on linux
Type "help", "copyright"
>>> a = 60
>>> b = 13
>>> print(a&b)
12
>>> exit()
```

```
▶ a = 60
  b = 13

  print(a&b)

☐ 12
```

a = 0011 1100

b = 0000 1101

a&b = 0000 1100

Case structure

- Basically a series of if-then-else with some constraint. In practice, the choice between the blocks of instruction is guided by the value of a certain variable:

switch variable:

case val1:

statements 1

case val2:

statements 2

...

default:

default statements

```
If (variable == val1)
```

```
{
```

```
    Statements 1
```

```
}
```

```
else if (variables == val2)
```

```
{
```

```
    Statements 2
```

```
}
```

```
...
```

```
else
```

```
{
```

```
    Default statements
```

```
}
```

Example

```
int i;
i = 4;
switch (i)
{
    case 1:
        printf("vale uno \n");
        break;
    case 2:
        printf("vale due \n");
        break;
    default:
        printf("non uno non due\n");
        break;
}
```

```
redo@banquo:~/Lezioni/IntroProgrammazioneInformatca/teaching/
[redo@banquo csmall (master)]$ gcc -o swtchc swtchc.c
[redo@banquo csmall (master)]$ ./swtchc
non uno non due
[redo@banquo csmall (master)]$
```

LOOPS

Loops

- There are three different types: **while..do** , **do..while** e **for**
- **Not all languages necessarily have all three of these structures**
- **These structures allow to repeat a block of instructions until a condition occurs**
- Also in this case it is possible to **nest** more loops one inside the other

While..do e Do..while

- The block of instructions can also never be executed, since **the condition is checked at the beginning**, as long as the condition is true, the block of instructions is executed

WHILE (condition)

statements

END DO

- do..while instead **executes the block of instructions until the condition is false**

DO

statements

WHILE (condition)

Example

- A simple C example:

```
int i = 0, N = 10;
```

```
while (i != N)
```

```
{
```

```
    printf("%d \n", i);
```

```
    i++;
```

```
}
```

```
[redo@banquo csmall (master)]$ gcc -o whiledo whiledo.c
[redo@banquo csmall (master)]$ ./whiledo
0
1
2
3
4
5
6
7
8
9
[redo@banquo csmall (master)]$
```

Example

```
Type "help", "copyright"  
>>> while True:  
...     print("here")  
...     █
```

```
▶ while True:  
    print("here")
```

```
↳ here  
here  
here  
here  
here  
here  
here  
here  
here  
here
```

Example

```
Int i = 0, N = 10;
```

```
do
```

```
{
```

```
    printf ("%d \n", i);
```

```
    i++; // i = i + 1
```

```
} while (i >= N);
```

```
[redo@banquo csmall (master)]$ gcc -o dowhile dowhile.c  
[redo@banquo csmall (master)]$ ./dowhile  
0  
[redo@banquo csmall (master)]$
```

For loop

- It executes a block of instructions a number of times known from the beginning. Many programming languages force the programmer to use a counter.
- Generally there is a counter which is an integer variable whose value is "changed" step by step
- The end condition is generally determined by comparing the counter variable with a value

for (counter = startingvalue A endvalue STEP = stepvalue)

statements

end for

Example

```
int i;  
for (i=0; i<10; ++i)  
{  
    printf ("%d \n", i);  
}
```

```
[redo@banquo csmall (master)]$ gcc -o forloop forloop.c  
[redo@banquo csmall (master)]$ ./forloop  
0  
1  
2  
3  
4  
5  
6  
7  
8  
9  
[redo@banquo csmall (master)]$ █
```

Example

```
for i in range(10):  
    print(i)
```

```
└─ $ python loop.py  
0  
1  
2  
3  
4  
5  
6  
7  
8  
9
```

ARRAY

Array

- How can I easily handle information that is structured by nature? For example a complex number, or a vector or a matrix?
- Typical structured variables are arrays
 - For example, a vector of floating-point numbers in C can be declared as: `float v [10];`
 - We can then access the i -th element of the vector: `v [i-1] = 3.5;`
- Likewise I can define an array (two-dimensional array) as:
`float m [10] [10];`

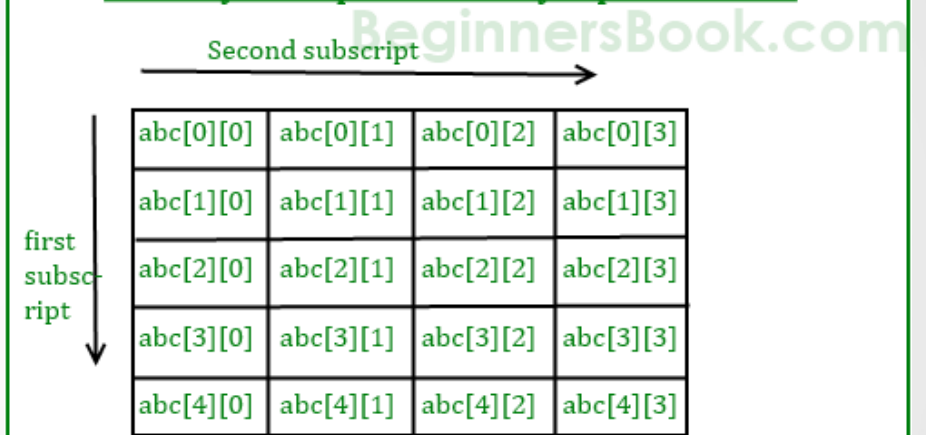

Array

Memory Location

200	201	202	203	204	205	206	▪	▪	▪
U	B	F	D	A	E	C	▪	▪	▪
0	1	2	3	4	5	6	▪	▪	▪

Index

2D array conceptual memory representation

Here my array is `abc[5][4]`, which can be conceptually viewed as a matrix of 5 rows and 4 columns. Point to note here is that subscript starts with zero, which means `abc[0][0]` would be the first element of the array.

Example

- Example loops to perform a scalar multiplication between vectors

```
float a[N], b[N];
for (i=0; i<N; ++i)
{
    a[i] = (float)rand()/(float)(RAND_MAX/N);
    b[i] = (float)rand()/(float)(RAND_MAX/N);
}
s = 0.0;
for (i=0; i<N; ++i)
{
    s = s + a[i]*b[i];
}
```

```
[redo@banquo csmall (master)]$ gcc -o vct vct.c
[redo@banquo csmall (master)]$ ./vct
a[i] ==> 5.658107
b[i] ==> 6.109299
a[i] ==> 5.057681
b[i] ==> 1.796469
a[i] ==> 8.166862
b[i] ==> 1.834716
a[i] ==> 5.846529
b[i] ==> 4.221560
a[i] ==> 0.253342
b[i] ==> 3.162596
a[i] ==> 0.612762
b[i] ==> 0.836590
a[i] ==> 9.767909
b[i] ==> 9.780582
a[i] ==> 8.738890
b[i] ==> 0.530768
a[i] ==> 2.689885
b[i] ==> 0.923382
a[i] ==> 8.809632
b[i] ==> 5.625731
236.850830
```

Example

```
import random

N = 20

a = []
b = []

for i in range(N):
    a.append(random.randrange(1, 30))
    b.append(random.randrange(1, 30))

for i in range(N):
    print("%3d %3d"%(a[i], b[i]))

s = 0.0
for i in range(10):
    s = s + float(a[i]*b[i])

print("")
print("S = %.5e"%s)
```
